The query results are the same as the database snapshot in the cap3.pdf file.

- A superkey is a set of columns in a database table that uniquely identifies all rows in the table. A candidate key is a minimal version of the superkey, with the least number of columns possible that still uniquely identifies rows in the table, and a primary key is generally the candidate key that we, the designers of the database, choose to use as the identifying column(s) for each row of the table.
- My hypothetical database is a list of science fiction books, SciFiBooks. The columns would be as follows: bookID, integer, not nullable; title, text, not nullable; author, text, not nullable; publishDate, date, nullable (in the case that publish date is not available for some reason); and avgRating, decimal, nullable (in case a certain book has not been rated yet).

4. Explanation of relational rules:

- a. The first normal form rule tells us that a column in a relational database table cannot be made up of multiple attributes; they must be atomic data values, able to be represented by a single value in a single data type. For example, we could not have an object “person” – with multiple attributes – in a database column, since we can only store one value in each individual column. Thus, if we needed to store data about people in a table, rather than violating this law and storing several attributes in one column, we could make new columns for this data, or a new table altogether. This rule is important because it keeps our tables and data consistent – only one data value can be found at the intersection of any row and column.
- b. The “access rows by content only” rule states that we can only query for a database row by its content, not by its location. One example of this is that we could not query a database to give us row number 3 of a table, but we could ask it for the content in the row with an ID of 3. This way, if a row with a certain primary key was ever deleted, we will receive an empty response from the database, telling us that row no longer exists, whereas if we had been able to query for row number three, we would always get a response as long as the database is three or more rows long, giving us different data than we might have expected. This rule keeps our query results consistent, as we cannot ask for a row that does not exist.
- c. The “all rows must be unique” rule means just what the name implies: that all rows must be unique. This rule isn’t as strongly enforced as the others – most database systems will not stop anyone from breaking this rule – because there are some cases in which rows would need to be not unique, such as in a linking table where there may be several entries for a single primary key. Nonetheless, this rule is important to keep data consistent, since duplicate entries could have errors that make the data invalid. This rule can be broken more easily than the others, but there should always be good reasoning – and comments in the code – to justify it.
